## Abstract

Honeypots have been proven to be very useful for accurately detecting attacks, including zero-day threats, at a reasonable cost and with zero false positives. However, there are two pressing problems with existing approaches. The first problem is that timely detection requires deployment of honeypots in a large fraction of the network address space, which many organizations or ISPs cannot afford. The second problem is that attackers are evolving, and it has been shown that it is not difficult for them to identify honeypots and develop blacklists to avoid them when launching a new attack.

In response to these problems, we propose a new architecture that enables large-scale deployment at low cost, while making it harder for attackers to maintain accurate blacklists. The Honey@home architecture relies on communities of regular users installing a lightweight honeypot that monitors unused IP addresses and ports. Since it does not require the static allocation of valuable chunks of network address space,

and considering the success of other community-based approaches such as `seti@home` and `fold-ing@home`, our approach is well-suited for creating a large-scale honeypot infrastructure at low cost. Since participation in the system is dynamic as users come and go, it becomes harder for attackers to maintain accurate blacklists.

In this paper we discuss the current design of the Honey@home architecture, a preliminary implementation and describe the design issues that we faced especially with respect to infrastructure robustness, the challenges we have to deal with and the effectiveness of our approach.

## 1 Introduction

Due to the increasing level of malicious activity seen on today's Internet, organizations are beginning to deploy mechanisms for detecting and responding to new attacks or suspicious activity, called Intrusion Prevention Systems (IPS). Since current IPS's use rule-based intrusion detection systems (IDS) such as Snort [19] to detect attacks, they are limited to protecting, mainly,

against already known attacks. As a result, new detection mechanisms are being developed for use in more powerful reactive-defense systems. The two primary mechanisms are honeypots [18, 13, 27, 21, 2, 8] and anomaly detection systems (ADS) [25, 24, 11, 15]. In contrast with IDS's, honeypots and ADS's offer the possibility of detecting (and thus responding to) previously unknown attacks, also referred to as *zero-day attacks*. Other approaches, like Dshield [1], try to correlate logs gathered from multiple points and create a summary of most attacked ports and most popular attacking sources. However, such systems are able to detect the source and destination of attacks, not their content.

Honeypots have been shown to be very useful for accurately detecting attacks, including zero-day threats, at a reasonable cost and without false positives, unlike IDS's and ADS's. However, there are two pressing problems with existing approaches. First, the effectiveness of honeypots heavily depends on the unused IP address space they monitor. Unused IP address space can be found in almost every organization, institution and public body due to underutilized or even totally empty subnets. However, the deployment of honeypots requires both administrative expertise and dedicated resources that many organizations cannot afford. The second problem is that attackers are evolving, and it has been shown that it is not difficult for them to identify honeypots and develop blacklists to avoid them when launching an attack. Although there are approaches to harden the identification of honeypots, recent work has shown that it is relatively straightforward for attackers to detect the placement of certain types of sensors [10, 20].

In response to these problems, we propose a new architecture that enables large-scale deployment at low cost, while making it harder for

attackers to maintain accurate blacklists. The Honey@home architecture relies on communities of regular users installing a lightweight honeypot that monitors unused IP addresses and ports. Users only need to install a lightweight daemon that runs in the background and is responsible for grabbing an unused IP address, forwarding the traffic of that space to a honeypot core and injecting the responses coming from that core back in responding to the attackers.

In this paper we discuss the current design of the Honey@home architecture, a preliminary implementation, the design issues that we faced especially with respect to infrastructure robustness, and present our early deployment experiences.

## 2 Honey@home design

Honey@home is designed simple and lightweight, as it mainly targets on typical home users or administrators unfamiliar with honeypot technologies. In a nutshell, Honey@home forwards traffic to unused IP addresses or unused ports to a honeypot farm and sends the answers provided by the honeypots back to the attacker. It is a software package that needs no special configuration to run and can run on both Linux and Windows platforms. It is also non-intrusive as it runs in the background with minimal CPU, memory and network overhead. Our measurements have shown that Honey@home client requires less than 2% CPU utilization and nearly 10MB of main memory for Windows versions. Similar requirements apply for the Linux version as well.

## 2.1 Design requirements

Honey@home is a software client that is accessible by everyone, including malicious users. With that in mind, we need to fulfill three major requirements:

- The location of honeypots must remain hidden. If honeypots become known, attacker can try to manually compromise them, evade their detection mechanisms or flood them with junk traffic, forcing them to waste their time on useless traffic instead of serving Honey@home clients.
- The identity of Honey@home clients must also remain hidden. Once it is known, the attacker may blacklist them and make them “blind” during the time of a real attack outbreak. Honey@home should be undetectable – or at least very hard to detect – by attackers.
- Attackers must be prevented from automatically installing Honey@home in the machines they own. In case that the attackers own a botnet, they must be forced to setup Honey@home manually to each one of the bots.

These challenges make Honey@home a more complex architecture than a simple packet forwarder. We address all of the above issues in Sections 3. Before we proceed to the challenges, we describe the architecture thoroughly at Section 2.2. Apart from the three main requirements, we also need to address the issue that malicious traffic must not be able to infect any part of the architecture, namely Honey@home clients, honeypots and intermediate components.

## 2.2 Core architecture

Every Honey@home client is responsible for a single unused IP address (unused IP addresses are also referred as *dark*) or the unused port space of the machine it is installed on. All the traffic received by the client is tunneled to the centralized honeypots of Honey@home core through the Tor anonymization network[14]. The Tor network provides all the desired anonymity for both Honey@home users and honeypots. Details about Tor are provided in Section 3. Responses coming from the core are injected by Honey@home to the network so as to reach the originators of the traffic. The architecture of Honey@home is represented at Figure 1. Honey@home clients are connected through an SSL connection to the *SSL server* component. The SSL connection is passing through the TOR anonymization network. The server component handles the client connections and it is responsible for authenticating users and forwarding their packets to honeypots. Users are authenticated by supplying a key to the SSL server. The key is obtained after the user registers at the official website of Honey@home. All registration information and user keys are stored in a MySQL database. Once the user is authenticated, she is allowed to forward packets to the core and receive responses from the honeypots.

We run both low- and high-interaction honeypots to handle user’s packets. *Honeyd*[18] is used as low-interaction honeypot. Honeyd is a very popular and lightweight system with many interesting properties, such as network stack emulation. We use honeyd as a mechanism to filter out uninteresting traffic, such as TCP connections that do not complete the three-way handshake or attacks that can be easily emulated, for

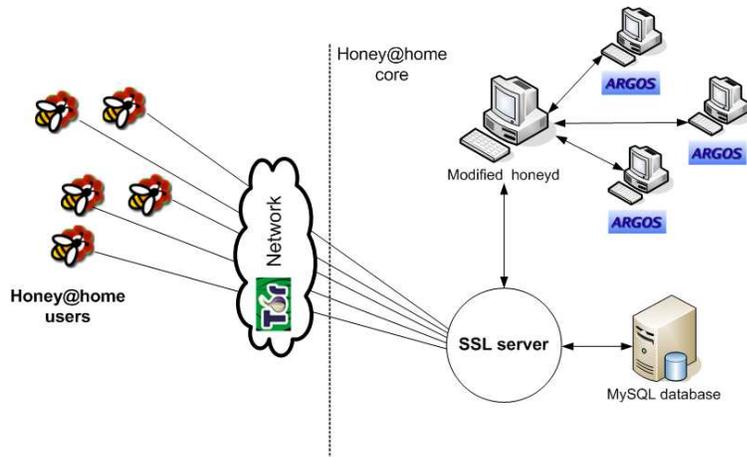

Figure 1: The Honey@home architecture

example SSH brute-force attacks. All the other traffic is forwarded to high-interaction honeypots. The forwarding is performed by a hand-off mechanism[9] we implemented inside honeyd. Honeyd creates a new connection with the high-interaction honeypot and sends all the application content it receives. The handoff is based on the destination port. For example, if an attacker wants to connect to port 445 or 139, the connection is forwarded to a high-interaction honeypot emulating the Windows XP operating system. As the choice of high-interaction honeypot is static, this means we may lose attacks for services that can run on multiple platforms. Examples of such services are web servers (Linux Apache or Windows IIS?), SMB sharing (Linux SAMBA or Windows sharing?) and many more. However, our choice is currently made based on popularity of applications in terms of users and attack instances. For our prototype system, we emulate a limited number of services and applications and more specific Linux telnet daemon, Microsoft Internet Information Server, MS-SQL server and the default Windows services. We

intentionally run unpatched versions of applications and services so we can observe attacks taking place.<sup>1</sup>

We chose Argos emulator[17] for high-interaction honeypot. Argos uses memory-tainting techniques and is able to track both known and unknown exploits. Argos is based on the idea that code coming from the network should never be executed. Once data from the network are treated as executable code, Argos raises an alert containing all relevant information about the attack and vulnerable application is restarted. As only the vulnerable application is restarted and not the whole virtual machine, the downtime of the vulnerable application is minimal. As Argos detects the attack before its code is executed, we have a core that is hard to infect. The only way to infect an Argos honeypot is to trigger an exploit on the underlying Qemu emulator [3] but this issue is beyond the scope of our work. In contrast with other approaches, like

<sup>1</sup>We plan to run fully patched versions in our production system so as to capture only fresh attacks.

Honeynets[2], that use bandwidth control and extrusion detection to mitigate effects of infection, our core is able to run with minor administration overhead. To improve the scalability of our architecture, we run multiple Argos systems in the core, each one being responsible for specific applications. As Argos has inherently slow performance, around 30x slowdown of applications, we need multiple instances in order to serve all clients. We also consider using traditional load balancing techniques to share load for the same target applications (like in Web server farms) and offload Argos by emulating known attacks through systems like Scriptgen[16]. Honeyd is not a bottleneck as it can serve around 2000 thousands TCP requests per second, according to [18].

### 2.3 Unused IP address space monitoring

Each Honey@home client is requesting an IP address from the local DHCP server (optionally it can be set to listen to a static IP address). Most broadband connection routers, like ADSL routers, organizations and institutes use DHCP servers to assign addresses. Every time Honey@home client starts, it requests an address from the local DHCP server. The main advantage of this approach is that user does not need to statically set an IP address, which may be even hard for him to find. Honey@home client can be stopped or started any time without interrupting the normal operation of user's network. Upon the client exit, the clients informs the DHCP server that the IP address is released. The procedure of how a Honey@home obtains an IP address is shown at Figure 2.3. The client first creates a pseudo-interface with a random MAC address and broadcasts a DHCP request (left

Figure 2: Honey@home client in action: Creating an pseudo-interface (left) and getting an IP address through DHCP server (right)

part of the Figure). When the DHCP response is received, client configures itself to wait for packets destined for the given address, 139.91.70.112 in our example (right part of the Figure).

The Honey@home client can be configured to claim an IP address statically or by using a BPF filter. Static allocation and BPF filter features are mainly targeted for more advanced users. For example, an administrator can setup a single Honey@home client in an unused subnet and set the BPF filter to cover all the addresses of that subnet. In that way, the unused subnet becomes utile in a few steps. As long as the client runs, the subnet monitored by the Honey@home client will contribute to the overall infrastructure.

As a short notice, Honey@home clients also receive legitimate traffic, such as broadcast ping or SMB queries. This traffic has to be white-listed and the decision can be made either locally or at the core. The Honey@home client can be configured not to forward traffic sent to specified ports. Additionally, Honey@home client can be configured to forward traffic sent only to a specific set of ports. By default, all traffic destined to the unused address claimed by Honey@home is sent to core. As Honey@home captures traffic directed to an unused IP address and not the packets destined for the actual IP address of the host running the tool, there are no privacy concerns. All traffic destined to unused addresses is by default suspicious. The only legitimate

traffic that is destined for unused addresses, according to our traffic traces, is attempts to connect to peer-to-peer ports. As peer-to-peer programs tend to have some sort of memory, like host caches of Gnutella, it is observed sometimes that some external hosts try to reconnect to an address that was used in the past, participated in a peer-to-peer network, but is not used anymore and thus claimed by Honey@home. If the user is concerned about privacy issues, she can configure the client not to forward traffic directed to these ports.

Honey@home can work even behind NAT. Hosts behind NAT cannot accept incoming connections from external hosts, only for ports that are explicitly forwarded to them through the router setup. For this case, Honey@home clients can automatically configure the local router to forward specific ports to the physical machine on which client is running using the UPnP protocol[5]. UPnP provides an API to configure the router to forward packets for specific address and ports and is supported by the majority of routers. However, modern routers have UPnP disabled by default for security issues as malware can also use it and make infected machines act like servers. For those users that are not privileged to change the router configuration, the Honey@home client is limited to capture suspicious traffic that is generated by internal infected hosts, for example local scans.

## 2.4 Unused port monitoring

Regular home users can usually claim one IP address. However, they can also contribute to the honeypot infrastructure by offering their unused port space. Ordinary users usually run a few applications that listen to specific ports. These applications include messengers that bind

a port for incoming file transfers and peer-to-peer clients. It is, thus, rare to find typical users that run a web server to their machine or an SMTP server.

Based on this observation and given that already infected hosts keep searching for new victims, it is expected that we may see connections destined to unused ports of the user. Honey@home client can be configured to listen to all unused port space (default) or to a set of ports specified by the user. It examines all incoming traffic (through the *pcap* library) and searches for connection attempts on the unused port space. If such an attempt is found then the traffic going to this port is forwarded to the core. Periodically, Honey@home client scans the host to obtain a list of used ports, similar to the way the netstat tool does, and update the list of unused ones.

The major concern around unused port monitoring is possible deniability. As an example, a user was running a peer-to-peer application for several hours ago and then disconnected from the peer-to-peer network. However, as such systems tend to have a sort of “memory”, incoming connections to the ports of his peer-to-peer application may still be arriving. Honey@home client sees that ports previously used by peer-to-peer applications are unused and forwards their traffic despite the fact that this traffic is legitimate. We are currently investigating these issues and we are experimenting on hold-on timers. Hold-on timers remember that a port was used  $k$  hours ago and even if it is currently unused, it is not forwarded. Another solution is port sampling, that is forward traffic from only a few unused ports. By default, Honey@home clients do not forward traffic destined to known sensitive ports, like Gnutella and eMule.

## 3 Dealing with challenges

In this Section, we provide details on how challenges described in 2.1 can be dealt with and specifically how we can hide honeypots (Section 3.1) and prevent automatic installation of Honey@home clients (Section 3.2).

### 3.1 Hiding honeypots

Hiding honeypots is essential for the viability of the architecture. The reason is twofold. First, we want to protect the core honeypots from immediate exposure. Although, we cannot protect them from Denial-of-Service attacks (the attacker can easily do DoS on the anonymization network), we make hard for the attacker to manually compromise our honeypots or use techniques that evade the deployed detection mechanisms. For Denial-of-Service attacks, the only measure we could take is not to accept clients that send data above a certain rate. By default, each Honey@home clients sends a few kilobytes per minute per monitored IP address and it is easy to detect misbehaving clients. Second, we envision Honey@home as an architecture that will act as a feeding mechanism for other systems as well. Currently, our prototype implementation is based on honeyd and Argos system but our architecture is flexible enough so other systems can plug in as well. A direct exposure of honeypots to users would possibly provide hints for detection mechanisms used in the core.

#### 3.1.1 Anonymous routing

Before we proceed on the approach we use for hiding honeypots, a brief introduction to anonymous routing is provided. The goal of anonymous routing is to protect the privacy of both

the sender and the recipient of a message, providing protection for eavesdropping in parallel. Messages are transferred from sender to recipient through an anonymization network and none in the middle of the path can identify the role of each participant (sender, receiver or forwarder).

The anonymization scheme we selected is onion routing, a technique based on a set of dedicated servers that route packets anonymously. Clients simply participate in the network without having to share their resources or help the network route packets. Onion routing uses dedicated software-based routers, called onion routers, that perform the anonymization process. We have also considered peer-to-peer anonymization schemes but they can lead to immediate exposure of Honey@home clients as they become the entities who form the anonymization network. Additionally, to the best of our knowledge, there are no widely deployed peer-to-peer anonymization networks.

Tor is the most popular and widely used implementation of onion routing and is used for anonymizing any application that uses the TCP protocol. The Tor network has several thousands users and around 2500 onion routers are deployed. Figure 3 illustrates how Tor works. At the sender side, user installs a SOCKS proxy that is used by the applications. This specialized proxy connects to Tor network to create an onion routing path. All communication between sender and onion routers and among routers is done using the TLS protocol (blue line). At the server side no deployment is needed. The last router of the path communicates with the recipient using the standard TCP/IP protocol (green line). Sender sends onions which are piled off along the path. The last router receives an onion with non-encrypted content and forwards it to the recipient. The response of the recipient fol-

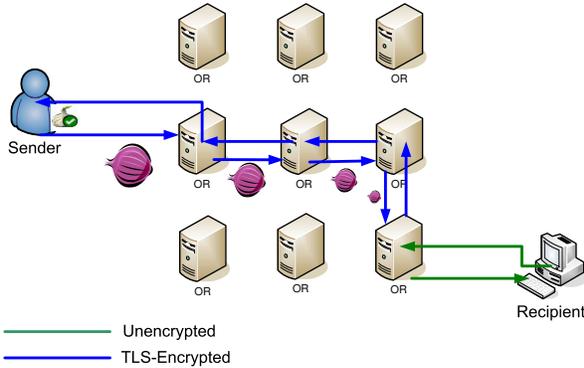

Figure 3: An overview of how Tor works. Client establishes a path of onion routers and sends onions, messages encrypted with public keys of all path’s routers. At each router the onion is piled off -decrypted by router’s public key- and forwarded to the next router. The last router has fully decrypted content and communicates directly with recipient through a standard TCP/IP connection.

lows the same path backwards.

### 3.1.2 Using Hidden Services

The way Tor was described earlier assumes that every sender knows the address of the recipient. This is not the case for our system, where address of honeypots must remain hidden. Tor offers a functionality called “hidden services”, that permits the recipient to hide its address. We have implemented Honey@home core as a hidden service. Honey@home clients only know the service descriptor of the core and will connect to it using a “xyz.onion” name. We use two safety features to protect our honeypots from attacks against TOR. First, the entry TOR node from honeypots to the introductory point is a trusted

node, maintained by Honey@home developers. This measure protects our infrastructure from Sybil attacks, where attackers users flood the TOR network with malicious servers so they can control the entry and exit nodes of TOR users. Second, we use SSL connection over the TOR network to ensure that even if the trusted router of the path is compromised, it cannot inspect the contents of the communication or understand that is a Honey@home client-Honey@home core communication.

### 3.2 Preventing automatic installations

In the case that an attacker owns a botnet, she can automatically install Honey@home clients in all bots if no measure for preventing automatic installation is taken. Massive deployment of Honey@home client to a botnet will cause deniability issues at the core. While the core does not suffer from false positive problems (specially crafted traffic that can trigger false alerts), its capacity in processing power is limited. To prevent attackers from massive installations, Honey@home clients are verified to the core by providing a registration key. The registration can be done at the official site of Honey@home. We employ Enhanced CAPTCHAs[7] techniques for the registration process. Additionally, two or more users with the same registration key cannot be connected with the core at the same time.

## 4 Deployment

We have deployed Honey@home to several institutions and organizations geographically dispersed. Clients cover diverse sizes of IP address space, ranging from a single address up to several

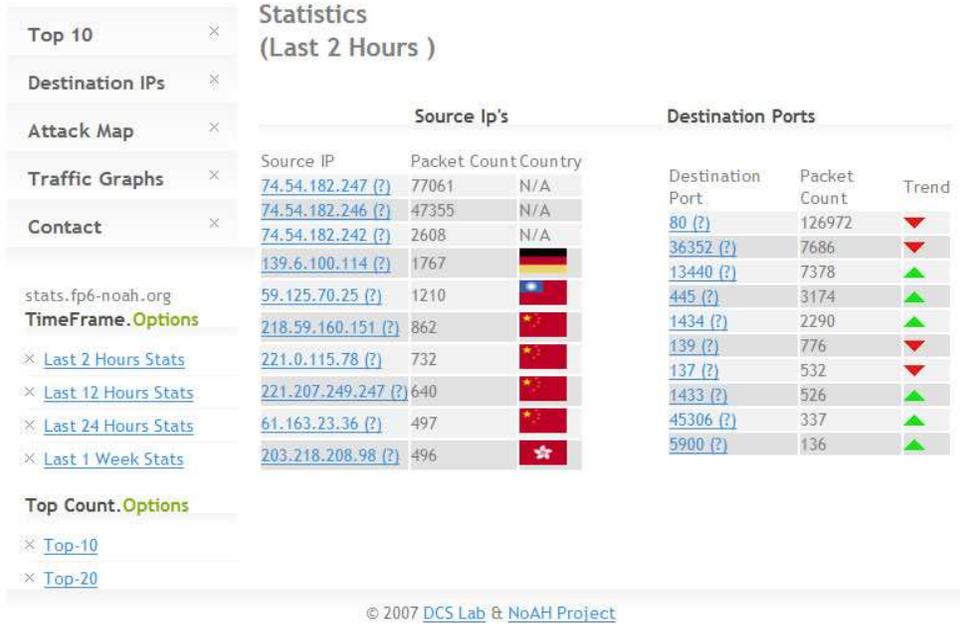

Figure 4: Top 10 source IP address and destination ports for an interval of 2 hours

/24 subnets. So far, we have 3 clients located in USA, 1 in Czech Republic and 4 clients in Greece. Although the number of clients seems small, the total IP address space monitored is 3074 addresses. We expect this number to grow as more people install Honey@home.

For each client we keep a number of statistics. More specifically, we are interested in top source IP addresses, in terms packets they send, and more popular destination ports. Furthermore, transfer protocol breakdown and backscatter traffic rate are also plotted. A screenshot of statistics for a client located in Greece can be seen at Figure 4. This Figure displays the most prevalent source IP addresses and more popular destination addresses for an interval of 2 hours. Same statistics can be displayed for

different time intervals, namely for 12 hours, 1 day and 1 week. Based on geolocation database of GeoIP, the origin country of the attacker is displayed next to the packet count. An interesting feature is the trend in destination ports. The trend reveals if that particular port receives more traffic in comparison with the previous time interval.

Based on the geolocation information from source IP addresses, we can construct a geographical map of attackers for each client. An example can be seen at Figure 5. Each country is colored differently as a function of the distinct number of IP addresses located in that country. Countries that host no attackers are colored in white, while most “active” countries are colored in red. We construct the same plot for number

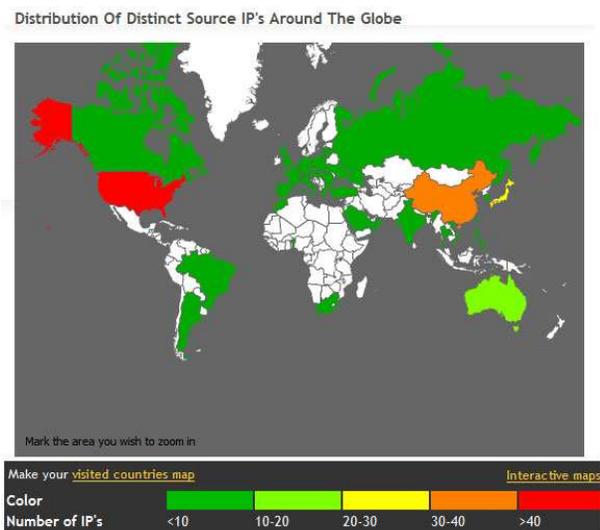

Figure 5: Colored map of attack countries based on the distinct number of attackers

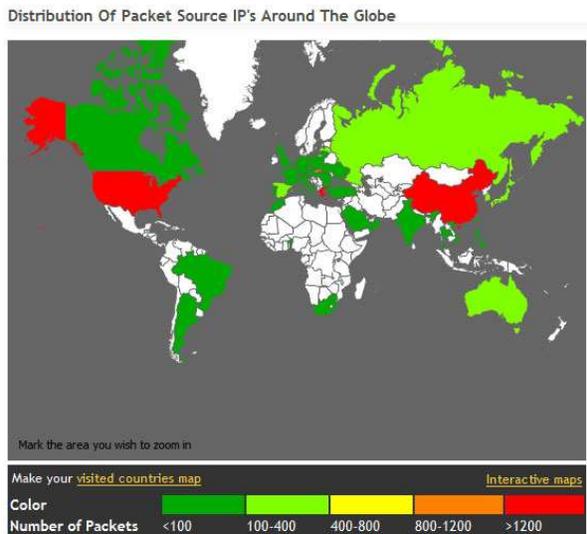

Figure 6: Colored map of attack countries based on packets sent

of packets from each country instead of distinct IP addresses. An example is shown at Figure 6. We can observe that there is no direct correlation between these two steps. While few IP addresses may originate from a single country, Greece for example, these addresses produce a large volume of traffic. Thus, while some countries may appear green in Figure 5 they are colored in red in Figure 6.

Another interesting type of statistics is the backscatter traffic. Backscatter traffic includes all unsolicited packets that have both SYN and ACK flags on. Distributed infrastructures like Honey@home can reveal whether a DoS attack is taking place and with what properties. Figure 7 plots the backscatter traffic received by a client that monitors ten /24 subnets.

#### 4.1 Argos alerts

Apart from traffic statistics, the Honey@home core also produces alerts for received attacks. As our high-interaction honeypots are based on Argos, all exploit attempts that target Honey@home clients, and thus are tunneled to our core, produce an alert in a format specified by Argos. The alerts produced by Argos contain the memory fingerprint of a detected attack. All tainted system state is exported. Argos isolates the attacked process by only looking up memory pages accessible to it. This way the volume of exported data is reduced to exclude data that cannot be associated with the attack. Argos also tracks incoming network data. This means that it can track exactly to which byte in the network trace each tainted byte corresponds from the moment it enters the system via the network

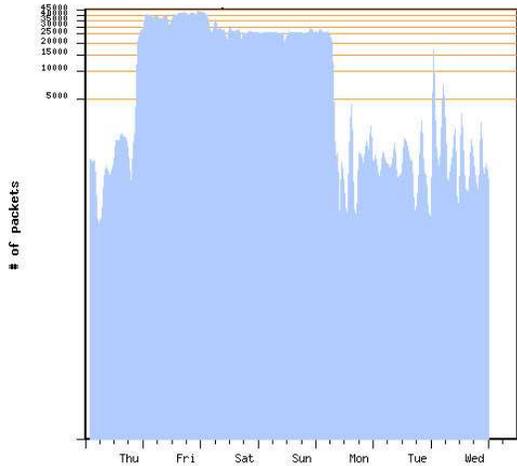

Figure 7: Backscatter traffic received by a Honey@home client that monitors ten /24 subnets for 1 week

card. Thus, for each attack we have the complete memory and network fingerprint plus some useful meta-data, like what service was targeted, which operating system was used and the time and date of the attack.

## 5 Related Work

In [23], the authors describe the risk to the Internet due to the ability of attackers to quickly gain control of vast numbers of hosts. They argue that controlling a million hosts can have catastrophic results because of the potential to launch distributed denial of service (DDoS) attacks and access any sensitive information that is present on those hosts. Their analysis shows how quickly attackers can compromise hosts using “dumb” worms and how “better” worms can spread even faster. In subsequent work [22], the same au-

thors show how a worm using pre-compiled lists of IP addresses known to be vulnerable can infect one million hosts in half a second.

The Honeynet project [2] is a non-profit organization that is devoted to the research concerning honeypots and their underlying architecture. Central aim of the project is the in-depth analysis of attacks and the capture of malware (e.g. IRCBots). The Honeynet project deploys an architecture that consists of a central gateway, “Honeywall”, and the honeypot network. Honeywall separates the network in which the honeypots are deployed from the rest of the network. Additionally, Honeywall performs access control of outbound connections from the honeypots and captures network data. The network behind Honeywall consists of high-interaction honeypots without emulation. Honeypots are also instrumented to trace their system calls through the Sebek tool [4].

Collapsar [26] is a project developed by the Purdue University aiming at the deployment and management of a large number of coordinating high-interaction honeypots across different network domains. The Collapsar architecture is comprised of a *Collapsar center*, a centralized operation center which hosts a network of high-interaction honeypots, and *traffic redirectors*. The redirector allows to virtually deploy honeypots in arbitrary networks and its basic function is to forward all traffic received to the honeypots of the Collapsar center. The redirector is implemented as a virtual machine based on the User-Mode Linux (UML [6]). High-interaction honeypots of the Collapsar center are based on either VMware or UML. Collapsar is somehow similar to our approach but has two major differences. First, redirectors are implemented as virtual machines. This approach requires more resources than our client and thus needs a ded-

icated machine to run. Second, redirectors are considered as trusted entities. Honey@home is designed to run in any workstation, thus it makes no assumption about trusting its clients.

Vigilante[12] is an infrastructure that aims at worm containment. The architecture of Vigilante is based on the collaboration of end hosts and makes no assumptions that collaborating hosts trust each other. The proposed approach has preferred to move from network-level to host-level in order to eliminate problems like encrypted traffic or lack of information about software vulnerabilities. End hosts act as honeypots; they run instrumented version of software that normally wouldn't run on the host. For example, a host can run an instrumented version of a database, not a common application for a normal host. One of the major contributions of Vigilante is the concept of self-certifying alerts (SCAs). SCAs are distributed among the collaborating of hosts and their novelty is that they can be verified by recipients. This property eliminates the need for trust between the hosts. Three types of SCAs can be identified: arbitrary execution control, arbitrary code execution and arbitrary function argument. Honey@home does not require clients to run instrumented versions of applications, which needs a handful of resources. We focus more on the scalability, supporting thousands of clients requiring minimum resources from them, and on the attack detection. Signatures generated by our architecture are similar to the ones described in [17], that is common subsequences between the memory pages around the overflowed buffer and the network trace of the attack. Such signatures are used at the network level to catch attacks. On the other hand, Vigilante detectors generate assembly-level filters that are used at the host level to block the attacks. Finally, our architec-

ture does not include any signature distribution mechanism at its current phase.

Bailey et al. in [9] propose a hybrid honeypot architecture for scalable network monitoring. In their architecture they filter prevalent content by using low-interaction honeypots and use a handoff mechanism to enable interaction between low and high-interaction honeypots. Low-interaction honeypots filter out uninteresting traffic such as unestablished TCP connections or payloads that have been observed many times in the past. Apart from honeypots, their proposed architecture introduces a control component. This component aggregates traffic statistics from low-interaction honeypots and analyzes all received data for abnormal behavior.

## 6 Conclusions

We have explored the design of Honey@home, a lightweight tool that enables users without expertise in honeypot technologies to contribute the fight against cyber-attacks. Honey@home claims unused IP addresses and ports, either dynamically or statically, and forwards all traffic directed to them to a centralized core of honeypots. The core consists of honeyd instances as low-interaction honeypots and Argos systems as high-interaction ones. As Honey@home can be used by anyone, including attackers, three major challenges need to be addressed: hide the identity of users, hide the identity of honeypots and prevent automatic installations. By using Tor, a well-known and deployed anonymization network used by thousands of users, we can hide the identity of both clients and honeypots. To prevent automatic installations, each client needs to be registered through the official website, where CAPTCHA techniques are used sim-

ilar to many popular large-scale services. Overall, Honey@home enables the creation of a distributed infrastructure with little effort and aims toward a scalable solution that overcomes the problem of classic honeypots, that is monitoring a small portion of unused IP address space.
